Abstract

Under the conditional independence assumption among local features, the Naive Bayes Nearest Neighbor (NBNN) classifier has been recently proposed and performs classification without any training nor quantization phases. While the original NBNN shows high classification accuracy without adopting an explicit training phase, the conditional independence among local features is against the compositionality of objects indicating that different parts of an object appear together. As a result, the assumption of the conditional independence weakens the accuracy of classification techniques based on NBNN.

In this work, we look into this issue, and propose a novel, Bayesian network for NBNN based classification to consider the conditional dependence among features. To achieve our goal, we extract a high-level feature and its corresponding, multiple low-level features for each image patch. We then represent them based on a simple, two-level layered Bayesian network, and design its classification function considering our Bayesian network. To achieve low memory requirement and fast query-time performance, we further optimize our representation and classification function, named relation-based Bayesian network, by considering spatial information between low-level features and by representing relationship between a high-level feature and its low-level features into a compact relation vector, whose dimensionality is same to the number of low-level features, e.g., four elements in our tests. We have demonstrated benefits of our method over the original NBNN and its recent improvement, local NBNN, in two different benchmarks. Our method shows significantly improved accuracy, up to 27\% point against the tested methods. This high accuracy is mainly thanks to considering the conditional dependences between high-level and its corresponding low-level features, which are intrinsic in many local features.

Keywords: Naive Bayes nearest neighbor, classifications, conditional dependency, Bayesian network

1. Introduction

Image classification is one of main research challenges in the field of computer vision. Its goal is to identify a category of a query image based on a classifier. Many classification techniques have been proposed and can be roughly divided into two families. The first one is learning-based (parametric) methods such as SVM \cite{1}, which require an intensive learning/training phase for optimizing classifier parameters. Another one is non-parametric methods such as nearest neighbor based classifiers that do not require a learning/training phase and work directly on image data. These two different techniques have different strengths, but learning based approaches typically achieve higher accuracy over non-parametric approaches, mainly because of its learning phase.

Recently, Boiman et al. \cite{2} proposed an efficient, yet accurate non-parametric method, the Naive Bayes Nearest Neighbor (NBNN) classifier, for image classification. Its main idea is that given a set of local image descriptors extracted from a query image, NBNN identifies the class of the query image based on simple schemes such as using the image-to-class distance without quantizing (e.g., bag-of-visual-words) descriptors that can lose original information encoded in the input, unquantized descriptors. In spite of the simplicity and the absence of learning/training phases in NBNN, it has been reported to achieve surprisingly remarkable performance in image classification.

NBNN has drawn attentions from researchers and has generated many follow-up studies. At a high level, recent studies have identified that the original NBNN has high computation complexity during testing query images, works mainly in balanced datasets, and has an unrealistic assumption of the independence among features. Some of these issues have been addressed by adopting a parametric version of the NBNN with a training step \cite{3}, class-to-image distance \cite{4}, the NBNN kernel \cite{5}, and local NBNN \cite{6}. Nonetheless, the conditional independence assumption has been understudied for the NBNN classification techniques according to the best of our knowledge.

For images, we typically extract various local features (e.g., dense SIFTs \cite{7}) for image classification. For example, Fig. 1 shows conditional dependence among such local features. The camera object consists of different parts, each of which is represented by multiple features. This is so-called compositional-ity of objects \cite{8}. Multiple features located locally can be grouped together to represent one part of the object, and several parts can be merged together to represent the object. As a result, the compositionality of objects can be represented by multiple layers. To consider such conditional dependence of local features, Naive Bayes can be transformed to a Bayesian network, where the Naive Bayes is the simplest form of Bayesian networks \cite{9}. Unfortunately, extracting the optimal dependence among local descriptors for Bayesian networks is an NP problem \cite{10}, and thus has raised significant technical challenges.

To consider the conditional dependence without requiring intractable time complexity, we propose to extend the original NBNN to a simple Bayesian network, two-level layered Bayesian network. For considering the conditional dependence, we extract two different types of local features, a single high-level
Figure 1: The camera (a) is constructed by several parts (b), whose local image features (c) are correlated with each other. To capture such conditional dependence, we use a two-level layered Bayesian network for the NBNN approach. (c) shows 3 by 3 image regions of a part of the object.

and multiple low-level features for an image patch. We identify conditional dependence between the high-level and low-level features, and represent them in a classification function in a similar spirit to the original NBNN. To achieve a low memory requirement and computational overhead, we optimize our representation by capturing relationship between the single high-level feature and multiple low-level features in a low-dimensional, relation vector, and reformulate our classification function with the relation vector. We have implemented our ideas and demonstrated that our method, relation-based Bayesian network, achieves significantly improved accuracy over the original and local NBNNs. Furthermore, our method does not require a learning phase as the original NBNN and has similar computational and memory requirement to that of the original NBNN. These results are achieved, mainly because we consider the conditional dependence among features based on our classification function with compact, yet effect relation vectors.

2. Background and Related Work

In this section we review prior techniques directly related to our method.

2.1. *Naive Bayes Nearest Neighbor (NBNN) Classifiers*

NBNN techniques \cite{2, 6, 5} are simple and intuitive for providing accurate classification results. Given a query image, \( Q \), the original NBNN assigns \( Q \) to one class, \( \hat{C} \), based on the Maximum Likelihood (ML) estimation among a possible class set indexed by \( C \):

\[
\hat{C} = \arg\max_C P(C|Q).
\]
Assuming a uniform prior over all classes and applying Bayes’ rule, Eq. 1 can be transformed to:
\[
\hat{C} = \arg\max_C \log(P(Q|C)).
\] (2)

Let \(\{d_1, d_2, \ldots, d_n\}\) denotes all the descriptors extracted from the query image \(Q\), which are assumed to be conditionally independent. Under the independence assumption, the ML estimation for NBNN can be transformed as follows:
\[
\hat{C} = \arg\max_C \log \left( \prod_{i=1}^{n} P(d_i|C) \right) = \arg\max_C \left[ \sum_{i=1}^{n} \log P(d_i|C) \right].
\] (3)

NBNN takes the Parzen Kernel estimator to compute the posterior probability for classifying images. As a result, the classifier is approximated as the following:
\[
\hat{C} = \arg\min_C \sum_{i=1}^{n} \|d_i - NN_C(d_i)\|^2,
\] (4)

where \(NN_C(d_i)\) is the nearest neighbor feature of \(d_i\) among features extracted from all the images assigned to the class \(C\). Fig. 2 visualizes the NBNN method with its data for each class.

In order to optimize the NBNN classifier for large-scale image classification, different techniques have been proposed. McCann et al. proposed the local NBNN by searching the nearest neighbors of the query image descriptors among the whole dataset to achieve the result in a much shorter elapsed time [6]. In [3], isotropic kernel bandwidths are introduced to reduce the bias in case of the unbalanced datasets with a training step. Tuytelaars et al. [11] proposed a NBNN kernel that can be combined with other kernels, and Wang et al. [4] proposed a class-to-image distance for multi-labeled image classification.

In this paper we look into the independence assumption among features, which has not been studied for NBNN techniques. Especially, we take an eye on the problem caused by the conditional independence assumption for image classification. Even before used in computer vision, NBNN classification techniques have been used in the text classification under the assumption that all the words
in one document are independent. Nonetheless, this assumption is incorrect in
many real-world problems. To address this issue, excellent improvements have
been proposed in the text classification in the last decade. Inspired by these
prior techniques, we aim to design a more accurate, yet efficient Bayesian clas-
sifier for image classification. Furthermore, we design our technique such that
it can be combined with most prior techniques such as local NBNN and other
distance metrics, and can achieve better accuracy over prior NBNN techniques.

2.2. Local Features and Dependences among Local Features

A set of local features is typically extracted to represent an image. Many
techniques as image representations have been proposed. Scale-Invariant Fea-
ture Transform (SIFT), for instance, is an algorithm proposed by Lowe [12] to
detect or describe local features as key points. While it has been extremely
successful, it can omit some discriminative features of one object, because some
discriminative features do not appear in key points. For example, in Fig. 3 the
feature $d_1$ is a discriminative feature of the camera because it has distinctive
patterns that can be found on the lens of cameras, but it may not be detected
as a key point. To address this issue, dense SIFT, which does not have scale
and location selection, is adopted to achieve higher discriminative power for
extracted features [7]. This kind of features are produced on a regular grid or
locations using a constant patch size with the same scale.

Suppose for Fig. 3 that local features of
$d_1, d_2, \ldots, d_9$ are extracted from a part, $D$, of
the camera based on the dense SIFTs. Also, suppose that
$d_1, d_2, d_3, d_4$ are nearest neigh-
bors to each other such that they can be
grouped together to represent a small image
region, $D'$, which is a part of $D$. In this ex-
ample of the camera class, the combination of
$d_1$ and $d_2$ has a higher probability to decide
the image category than having each one of
d_1 or d_2. Furthermore, having two features of
d_1 and d_2 can result in a higher probability to
detect the image category than having both
features of d_1 and d_9. Note that the feature
d_9 shows a reflected object on the lens and is
not a part of the camera object.

As pointed out in the prior example, the
dependences among near local features exist,
and the combination of local features can help
us to classify images better. It also shows that
the assumption of conditional independence
among all the local features can weaken the performance of the NBNN classifier.
To address this issue, we build a layered structure of features with different
scaled descriptors and utilize the local dependences to gain better classification
results.
2.3. Bayesian Network

Naive Bayes is the simplest form of Bayesian networks \([13, 14, 15, 16]\), and has only two layers: one parent node and other nodes. Its simple structure is constructed on the assumption that given the parent node, the other nodes are independent, which is called conditional independence.

Bayesian networks are structured and graphical models that can represent relations between several random variables. In a Bayesian network, each variable is conditionally independent of all its non-descendants given the value of all its parents. This translates into the following equation:

\[
P(X_1, \ldots, X_n) = \prod_{i=1}^{n} P(X_i | \text{parents}(X_i)),
\]

where \(X_1, \ldots, X_n\) are variables in the Bayesian network, and \(\text{parents}(X_i)\) indicates parent nodes of \(X_i\). In order to tackle the conditional independence assumption in NBNN, we use a simple Bayesian network considering conditional dependence among features to compute the probability.

Among various Bayesian network approaches, we have particularly chosen \(d\)-separation \([13, 14, 15, 16]\) to capture conditional dependence among features. For example, suppose that \(A\) and \(B\) are conditionally independent under parent node \(X\). Similarly, suppose that \(a_1, \ldots, a_4\) are conditionally independent under their parent node \(A\), and \(b_1, \ldots, b_4\) are too under their parent node \(B\). We can then call that \(X\) and \(\{a_1, \ldots, a_4 \cup b_1, \ldots, b_4\}\) are \(d\)-separated by \(A\) and \(B\). The probability of having \(X\) in this context can then be computed as follows:

\[
P(X, A, B, a_1, \ldots, b_4) = P(X)P(A, B | X)P(a_1, \ldots, a_4 | A)P(b_1, \ldots, b_4 | B).
\]

3. Bayesian Network for Image Classification

In order to tackle the weak assumption of conditional independence in NBNN, we need to find out the dependences among local features. Searching for the optimal dependences in the image, however, is an NP problem \([9]\). Instead, we model the dependences among local features by a simple Bayesian network, especially with \(d\)-separation (Sec. 2.3). In this section, we introduce how to build and use our simple Bayesian network with local features. We then propose our optimization, relation-based Bayesian network, for effectively and efficiently considering the conditional dependence (Sec. 3.3).

3.1. Our Bayesian Network Model

Given an image, descriptors can be computed with different scales or at different locations. For our goal of considering the dependency among features, we extract features for a region in two different scales. Specifically, given a region, we represent the region with a single dense SIFT descriptor as well as four dense SIFT descriptors from 2 by 2 subdivided regions of the region, as shown in Fig. 4. We call the feature with a higher scale a high-level feature,
Figure 4: For a image region, $I_R$, we extract a high-level feature, $d_i$, from the region, and four low-level features from 2 by 2 subdivided regions of the same region $I_R$. These features with two different scales represent the same region $I_R$.

and features with the smaller scale low-level features. We adopt this simple, but two-level layered representation to consider conditional dependence and compositionality of objects.

In this paper, we use the simplest form of the Bayesian network with the two-level layered local features based on the descriptors of dense SIFT. We have also found that features in the second layer are well correlated because they are located next to each other. Furthermore, we extract one high-level feature with four low-level features in the same patch for simplicity.

We use $d_i$ to denote the high-level feature of $i$-th image patch. $d_i$ is a $n \times 1$ vector assuming that the dense SIFT has $n$ dimensionality. We partition the $i$-th image patch into 2 by 2 sub-patches, and extract a low-level feature for each sub-patch that is also represented by an $n$ dimensional dense SIFT.

As a result, we have four different low-level features, $d_{i,1}, d_{i,2}, d_{i,3}, d_{i,4}$, from the same, $i$-th image patch. We model our Bayesian network of local features in two layers. The first layer is constructed by the high-level feature, and is called a parent node. It is linked with the second layer. The second layer consists of a set of low-level features, which are named as children nodes. The layered structure makes a Bayesian network and we use this structure of features for non-parametric classifiers. The left side of Fig. 5 shows our two-level layered Bayesian network.

3.2. Classification using Our Bayesian Network

We now explain how to utilize our Bayesian network, two-level layered structure of local features, to classify images. Before running the classification algorithm, we first prepare a set of labeled images for each class in a similar manner to the original NBNN. Unlike the original NBNN, the labeled image set for each class is represented by our layered image representation with their high-level and low-level features.

Given a query image $Q$, our method with the two-level layered Bayesian network assigns $Q$ to one class based on the maximum likelihood estimation under the uniform prior among a possible class set indexed by $C$ and the Bayes’ rule. We then get $\hat{C} = \arg\max_c \log[P(Q|C)]$, as the original NBNN.

According to our two-level layered Bayesian network, we have the conditional dependence between the high-level and low-level features. Given a high-level
feature $d_i$, it is associated with its four children nodes $d_{i,1}, d_{i,2}, d_{i,3}, d_{i,4}$. We then reformulate the aforementioned classification equation as the following:

$$\hat{C} = \arg\max_C \log[P(d_i|C)P(d_{i,1}, d_{i,2}, d_{i,3}, d_{i,4}|d_i)].$$ (7)

Under the parent node $d_i$, four children nodes $d_{i,1}, d_{i,2}, d_{i,3}, d_{i,4}$ are independent as the following:

$$P(d_{i,1}, \ldots, d_{i,4}|d_i) = \prod_{j=1}^{4} P(d_{i,j}|d_i).$$ (8)

Additionally, an image can have $n$ different high-level features, which are assumed to be independent. We therefore get the following classification:

$$\hat{C} = \arg\max_C \log \left[ \prod_{i=1}^{n} P(d_i|C) \prod_{j=1}^{4} P(d_{i,j}|d_i) \right]$$ (9)

$$= \arg\max_C \left[ n \sum_{i=1}^{n} \log P(d_i|C) + \sum_{j=1}^{4} \log P(d_{i,j}|d_i) \right].$$

In this equation we have two different conditional probability. We also use the Parzen window estimator with a Gaussian kernel $K$ and approximate it with a nearest neighbor, $NN_C(d_i)$, from $d_i$ in the class $C$, as adopted in the original NBNN. The conditional probability of descriptor $d_i$ under the class $C$ is then represented as follows:

$$\hat{P}(d_i|C) = \frac{1}{L} K(d_i - NN_C(d_i)),\quad (10)$$
Algorithm 1 Our two-level layered, Bayesian network for image classification.

1: Compute two-level layered descriptors of high-level descriptors $d_1, \ldots, d_n$ and their low-level descriptors $d_{1,1}, \ldots, d_{1,4}, d_{2,1}, \ldots, d_{n,4}$
2: Compute the nearest neighbor (NN) of the descriptor
   (a) $\forall d_i, \forall C$, compute the NN of $d_i$, $NN_C(d_i) \equiv d_t$, in $C$.
   (b) for each $d_{i,j}$ in $d_i$, compute the NN of $d_{i,j}$, $NN_{d_t}(d_{i,j})$, in the low-level descriptors of $d_t$.
3: $\hat{C} = \arg\min_C \left[ \sum_{i=1}^n \left( \|d_i - NN_C(d_i)\|^2 + \sum_{j=1}^4 \|d_{i,j} - NN_{d_t}(d_{i,j})\|^2 \right) \right]$ where $L$ is the number of high-level descriptors in the training (labeled) set for the class $C$. In a similar manner, we define the conditional probability of low-level descriptor $d_{i,j}$ under its parent node descriptor $d_i$ as the following:
\[
\hat{P}(d_{i,j}|d_i) = \frac{1}{l} K(d_{i,j} - NN_{d_t}(d_{i,j})), \tag{11}
\]
where $l$ is the number of children nodes that the descriptor $d_i$ has and set to be 4 in this paper. For evaluating the first conditional probability term, we already identify the nearest neighbor, $NN_C(d_i)$, of high-level descriptor $d_i$ under the class $C$. In the labeled image set, $d_t \equiv NN_C(d_i)$ has four children nodes $d_{t,1}, \ldots, d_{t,4}$. As a result, $NN_{d_t}(d_{i,j})$ indicates the nearest neighbor of the low-level feature $d_{i,j}$ among low-level features $d_{t,1}, \ldots, d_{t,4}$ of $d_t$.

The kernel $K$ is chosen as a Gaussian Kernel, which is substituted into Eq.10 and Eq.[11]. We then have the following classification function:
\[
\hat{C} = \text{argmax}_C \left[ \sum_{i=1}^n \left( \log \frac{1}{L} e^{-\frac{1}{2\alpha^2} \|d_i - NN_C(d_i)\|^2} + \sum_{j=1}^4 \log \frac{1}{l} e^{-\frac{1}{2\alpha^2} \|d_{i,j} - NN_{d_t}(d_{i,j})\|^2} \right) \right]
\]
\[
= \text{argmin}_C \left[ \sum_{i=1}^n \left( \|d_i - NN_C(d_i)\|^2 + \sum_{j=1}^4 \|d_{i,j} - NN_{d_t}(d_{i,j})\|^2 \right) \right]. \tag{12}
\]

In summary, our two-level layered Bayesian network for image classification is shown at Algorithm 1.

Issues of the proposed Bayesian network. The proposed Bayesian network considers conditional dependence between high-level and low-level features. Its time and memory complexity, however, are higher than those of the original NBNN. Specifically, we need to perform four more nearest neighbor search to compute $NN_{d_t}(d_{i,j})$ for low-level features. While each search of these operations has only a small data, i.e., four low-level features for each high-level feature $d_i$, we need to perform a few thousands operations overall, since each image can have thousands of high-level features. Furthermore, storing those low-level features requires extra memory space.
Additionally, low-level features extracted from a region have location information. This location information, unfortunately, is not explicitly encoded in the classification function of Eq. 12. On the other hand, four low-level features and their corresponding high-level feature are extracted from the same image region. We utilize such information to lower the memory requirement and computational overhead down in the subsequent section.

3.3. Optimization: Relation-based Bayesian Network

We extract a single high-level feature and its corresponding four low-level features from each image patch. As a result, they have intrinsic dependence or correlation between them. We therefore utilize such relationship for achieving high accuracy and even for lowering computational and memory overheads down.

To utilize such relationship, we propose to use a relationship vector, \( r \). Specifically, each descriptor vector, \( d \), for a high-level feature has a \( n \times 1 \) dimensionality, where \( n \) corresponds the dimensionality of the employed feature, e.g., 128 for the used dense SIFT. When we concatenate four low-level features into a matrix representation, these concatenated low-level features, denoted by \( d' \), live in a \( n \times 4 \) matrix space. We then represent the relationship between \( d \) and \( d' \) by \( r \), which is a \( 4 \times 1 \) vector, as the following:

\[
\text{\( r = d'^T \times d. \)} \tag{13}
\]

By applying the pseudoinverse, \( d^+ \), of \( d \) to the right side of each term in the above equation, and taking the transpose, we get the following equation:

\[
\text{\( d' = d'^T \times r^T, \)} \tag{14}
\]

where \( d^+ \equiv V \Sigma^+ U^* \) is computed by applying the singular value decomposition on \( d; V, \Sigma, U \) are 128 by 128, 128 by 1, and 1 by 1 matrices, respectively.

Given the equation (Eq. 14), a high-level feature, \( d_i \), extracted from \( i \)-th patch, and its relationship vector, \( r_i \), we can represent the concatenated four low-level features with the SVD counterpart of \( d_i^T \), \( d_i^+T \), multiplied by \( r_i^T \). The classification function shown in Eq. 12 can be then transformed as follows:

\[
\hat{C} = \arg\min_{C} \left[ \sum_{i=1}^{n} (\|d_i - NNC(d_i)\|^2 + \|d_i^+T \times r_i^T - NND(d_i^+T \times r_i^T)\|^2) \right]. \tag{15}
\]

Performing SVD for each high-level feature \( d_i \) is, however, a time-consuming process. Fortunately, when the first term has the low value, we can assume that \( d_i \) and \( d_i = NNC(d_i) \) are similar, and \( d_i^+ \) and \( d_i^+ \) are so accordingly. Based on this assumption, we simply drop \( d_i^+ \) and \( d_i^+ \) in the second term. Based on this simple approximation, we can avoid the expensive SVD computation. Furthermore, there is always a single relationship vector, \( r_i \), associated with each high-level vector \( d_i \) and thus the nearest neighbor operation in the second term
**Algorithm 2** Optimized, relation-based Bayesian network for image classification.

1: Compute high-level descriptors $d_1, \ldots, d_n$ and their relation vectors $r_1, \ldots, r_n$ with corresponding low-level descriptors.

2: Compute the nearest neighbor (NN) of the descriptor

   (a) $\forall d_i \forall C$, compute the NN of $d_i$, $NN_c(d_i) \equiv d_t$, in $C$.

   (b) Fetch the relation $r_t$ of $d_t$ in $C$

3: $\hat{C} = \arg\min_C \left[ \sum_{i=1}^{n} (||d_i - NN_c(d_i)||^2 + \lambda ||r_i - r_t||^2) \right].$

reduces to simply returning $r_t$. Since $r_t$ is a 4 by 1 vector, we can drastically reduce the memory requirement.

As a result, we have the following, efficient classification function:

$$\hat{C} \approx \arg\min_C \left[ \sum_{i=1}^{n} (||d_i - NN_c(d_i)||^2 + \lambda ||r_i - r_t||^2) \right],$$

where $\lambda$ is a weight factor for the second term. Note that our assumption breaks when two high-level features are similar, but their relationship vectors are significantly different. To mitigate this problem, while this problem occurs rarely in practice, we set $\lambda$ value to be less than one. We have tried out different values within a range $(0, 1)$ and found 0.25 to show the best accuracy.

As shown in the right side of Fig. 5, our optimized representation is quite simple. Instead of storing both high-level and low-level features, we compute the relation vector between them, and represent labeled image sets solely with high-level features and their associated relation vectors. This simple approach saves a lot of space and requires a minor computational overhead over the original NBNN, while considering conditional dependence among neighboring features.

Our final relationship based Bayesian network for image classification is summarized in Algorithm 2.

4. Results and Discussions

We conducted a series of tests on the Intel Quadcore i7 3.60GHz with 16GB memory. We use the FLANN [17] library utilizing multiple, randomized kd-trees, to efficiently compute approximate nearest neighbors. In our experiments, we built the indexes of kd-trees with the labeled data set, and we load and use those pre-built data structures for performing nearest neighbor search in an efficient way.

**Benchmarks.** We use the Caltech101 and Caltech256 benchmarks for various tests. Caltech101 contains 101 categories and about 40 to 800 images per category. Caltech256 has a set of 256 object categories, each of which has at least 80 images. By following the experiment protocol of the original NBNN, we randomly choose 15 (or more numbers of) images per category as labeled data.
Table 1: Classification results of different methods with 20 test images in Caltech-101.

for all the tests. For query images we randomly choose 20 test images from the benchmark except for already chosen training (labeled) images. We have iterated this process two times, and have measured the average precision for each class for accuracy comparisons.

Descriptor. For each image we extract densely sampled SIFT descriptors [7]. The patch size of each high-level feature is set to be $32 \times 32$ pixels, and the patch is divided into 2 by 2 regions, each of where we extract a low-level patch. We extract high-level features at every 16 pixels along X and Y directions, and thus regions of high-level features have overlaps. If the size of an image is smaller than 200 we resize it to 200, and when the size is bigger than 450, we resize it to 450. In these configurations an image contains 300 to 2000 SIFT descriptors of high-level features.

4.1. Experimental Results

To show benefits of our method, we compare different types of our method against the other state-of-the-art NBNN methods, as the following:

- NBNN. The original NBNN method [2]
- LNBNN. The local NBNN method, a recently improved NBNN method [6]
- BN: Our two-level layered Bayesian network.
- RBN: Our relation-based, optimized Bayesian network that considers conditional dependence for the original NBNN.

We have implemented NBNN and LNBNN based on the guideline suggested by their corresponding papers.

Table 1 shows classification accuracy of different tested methods with 20 test images in Caltech101. All the methods achieve higher accuracy as we use more labeled data images, and our method achieves highest accuracy. For the case tested with 30 labeled images for each class, our relation-based Bayesian network RBN shows 72.31%, which is more than 19% point higher than that of the original NBNN. Compared with LNBNN, our method achieves more than 16% point higher accuracy. This improvement is mainly thanks to considering the conditional dependency between high-level and low-level features.
Table 2: Classification results by two methods LNBNN and RBN with 20 test images in Caltech-256

Table 2 shows the classification accuracy of LNBNN and RBN with 20 test images in Caltech256. We do not test NBNN and BN, since they run slow with this bigger benchmark and they are outperformed by LNBNN and RBN, as demonstrated in Caltech101. Compared with LNBNN, our method RBN shows higher accuracy over LBNN across all the tested setting. Especially with 50 labeled training data images for each class, our method achieves 57%, which is 27% point higher than that of LNBNN.

Fig. 6 shows the classification accuracy of different classes under 15 labeled training images and 20 test images. We can observe that in most cases, LNBNN performs better than NBNN, but shows worse results in some classes such as chair and cup. On the other hand, our method RBN shows better or similar accuracy over the tested prior method across different classes. This also demonstrates the robustness of our approach of considering conditional dependence among features.

In terms of runtime computational overheads, LNBNN is the fastest method over other methods including ours. Because the time complexity of our method is similar to NBNN, we gain the classification result for each query in the similar performance with NBNN. Our method RBN takes 2.5 s for a query image extracted by 1000 patches on average in Caltech101. We have tested adopting the idea of the local NBNN using a single, global kd-tree for all the classes. While it improves the runtime performance of our method, its accuracy was much lower than that of our RBN method. As a result, we maintain kd-trees, each of which is constructed from labeled images of each class, as proposed by the original NBNN.

5. Conclusion

We have proposed our two-level layered Bayesian network to consider conditional dependence among features for NBNN classification. Our method extracts a high-level feature and four low-level features for each image patch. We proposed our classification function based on nearest neighbors and our Bayesian network. To utilize spatial information between high-level and low-level features, and optimize the performance and memory requirement of our Bayesian network, we modify our classification into relation-based Bayesian network by using the $4 \times 1$ relationship vector between high-level and its corresponding four low-level features. We have demonstrated benefits of our relation-based Bayesian network with two different benchmarks and showed that our method
Figure 6: Classification results by NBNN, LNBNN, and RBN with different classes. These results are acquired with 15 training (labeled) images for each class in Caltech101.

significantly improves the accuracy over the original and local NBNNs. This result is achieved mainly thanks to considering conditional dependence between features.

As limitations and future work of our research direction, we would like to further utilize existing dependence among features. While we utilized conditional dependence between high-level and its low-level features, our method does not consider dependence among high-level features. We would like to address this issue for higher accuracy. In the current work, we have mainly tested two levels for our representation. We would like to build more layers of features and see whether it can improve the classification accuracy.

While our runtime performance is in a similar order to that of the original NBNN, our current approach can take a few second for classifying a query image. We would like to adopt recent hashing technology [18] to accelerate our method and to handle large-scale benchmarks.
